1 Introduction

This document is intended to give a short overview of the methods found in the GPLTR package. The acronym GPLTR is designed for — Generalized Partially Linear Tree-based Regression model —.

The GPLTR programs build classification or regression models of a very general structure using a three stage procedure with several additional tools (see (Mbogning et al. 2014)); the resulting model is an hybrid model combining a generalized linear model with an additional tree part on the same scale. The model was first proposed by (Chen et al. 2007) for genetic epidemiology studies in order to assess complex joint gene-gene and gene-environment effects taking into account confounding variables. In practice, the GPLTR models represent a new class of semi-parametric regression models that integrates the advantages of generalized linear regression and tree-structure models. To our best knowledge, there is currently no implemented package dealing with this kind of model. The available classical tree-based methods do not provide a way for controlling confounding factors outside the tree part (the final tree is generally a mixture of confounders and explanatory variables lacking of clear interpretation and resulting in a distorted joint effect).

We also proposed an ensemble method (see (Mbogning et al. 2015)), mainly the bagging, to address a classical concern of tree-based methods, their instability. the Bagged GPLTR is proposed with several scores of variable importance for prediction and variable selection in the framework of the GPLTR model.

2 GPLTR model

Denote \mathbf{Y} the outcome of interest, \mathbf{X} a set of confounding variables, and \mathbf{G} the explanatory variables. The model fitted inside the GPLTR package is specified by:

$$g\left(\mathbb{E}\left(\mathbf{Y}|\mathbf{X},\mathbf{G}\right)\right) = \mathbf{X}'\theta + \beta_T F\left(T\left(\mathbf{G}\right)\right),\tag{1}$$

where $g(\cdot)$ is a known link function (generalized linear model), $F(T(\mathbf{Z}))$ is a vector of indicator variables representing the leaves of the tree $T(\mathbf{G})$.

The variables considered in the linear part (confounding variables or variables we wish to control) of the model (1) have a direct impact on the structure of the tree, beginning by the split criterion and ending by the pruning procedure.

3 Fitting methods

The method we used in this package to fit the model (1) can be summarized into three major steps:

- **Step1** Fit the linear part and build a maximal tree within an iterative procedure by playing on several offsets terms. The nodes of the tree are splitted by maximizing a deviance criterion, while an intercept coefficient is fitted inside the node using the corresponding glm with the linear part considered as offset.
- **Step2** In order to prune back the maximal tree obtained previously, we use a forward procedure to build a sequence of nested subtrees.
- Step3 The optimal tree is selected, using either a BIC criterion, a AIC criterion, a K-fold Cross-validation procedure on the underlying GPLTR models corresponding to the nested trees sequence. The original parametric bootstrap test procedure proposed by Chen et al. is also available.

We further propose a procedure to test the joint effect of the selected tree while adjusting for confounders. The users are encouraged to read the recent paper of (Mbogning et al. 2014) for a more thorough explanation about the model and the methods.

Table (1) represents a brief summary of the main functions available inside the GPLTR package. A more complete description is available inside the package documentation.

	Table 1: Main function in the GPLTR package
Function	Description
pltr.glm	Fit an unprunned pltr model
best.tree.BIC.AIC	Prunned back the unprunned pltr with a BIC or AIC criterion
best.tree.CV	Prunned back the unprunned pltr with a CV procedure
best.tree.bootstrap	prunned back the unprunned pltr with a parametric bootstrap procedure
p.val.tree	Test the joint effect of the selected tree part while adjusting for confounders
bagging.pltr	Aggregate a set of pltr models
$predict_bagg.pltr$	Predict new features with bagging pltr predictor
VIMPBAG	compute several variable importance score with the bagging pltr predictor

4 Illustration via several examples

In the following, we will present the results obtained on the publicly available "burn" Data Set (Times to Infection for Burn Patients from the book of Klein and Moeschberger (Klein and Moeschberger 2003)). This dataset comes from a study (Ichida et al. 1993) that evaluates a protocol change in disinfectant practices for a cohort of 154 patients. A complete description of the data is also available inside the GPLTR package documentation.

In this example, the dependent variable is the administration of prophylactic antibiotic treatment (D2: yes/no), the confounding variable is the gender (Z2: male/female) and the potential explanatory variables are: ethnicity, severity of the burn as measured by percentage of total surface area of body burned, burn site (head, buttocks, trunk, upper legs, lower legs, respiratory tract), and type of burn (chemical, scald, electric, flame). In this analysis, we included gender as a confounding factor since this factor has already been described as related to infections among burn patients (Wisplinghoff et al. 1999). Such

adjustment for confounders cannot be performed within the classical CART framework.

Results obtained with the classical CART algorithm

First of all, we have fitted a classical tree model on the dependent variable D2, using the CART algorithm (Breiman et al. 1984) via the 'rpart' routines (Therneau and Atkinson 2013) of the R software:

```
> data(burn)
> head(burn, n = 10)
   Obs Z1 Z2 Z3 Z4 Z5 Z6 Z7 Z8 Z9 Z10 Z11 T1 D1 T2 D2 T3 D3
1
     1
        0
           0
               0 15

```

Figure 1: Tree obtained on the burn dataset with rpart.

```
> #par(mar = rep(0.1, 4))
>
> plot(rpart.burn)
> text(rpart.burn, xpd = TRUE, cex = .6, use.n = TRUE)
```

Figure (1) represents the tree obtained using the classical CART algorithm.

The tree is built by the following process: first the single variable is found which best splits the data into two groups (via the Gini index in the example). The data is separated, and then this process is applied separately to each sub-group, and so on recursively until the subgroups either reach a minimum size or until no improvement can be made.

Results obtained with our proposed method within the GPLTR package

A logistic partially linear tree-based regression model is fitted by using our proposed method:

```
> ## use example(GPLTR) to have a brief overview of the contain of the package.
>
> ## fit the PLTR model after adjusting on gender (Z2) using the proposed method
> ## ?GPLTR or ?pltr.glm to access the help section
> ## setting the parameters
>
> args.rpart <- list(minbucket = 10, maxdepth = 4, cp = 0,</pre>
                         maxcompete = 0, maxsurrogate = 0)
> family <- "binomial"</pre>
> X.names = "Z2"
> Y.name = "D2"
> G.names = c('Z1','Z3','Z4','Z5','Z6','Z7','Z8','Z9','Z10','Z11')
> ## Build the maximal tree with an adjustment on gender (Z2)
>
> pltr.burn <- pltr.glm(burn, Y.name, X.names, G.names, args.rpart =
                        args.rpart, family = family,iterMax =8, iterMin = 6,
                          verbose = TRUE)

```

- The underlying method behind the 'binomial' family above is a new one, different from those implemented inside the **rpart** package. The splitting criterion is based on a logistic deviance criterion considering the linear part as offset (Mbogning et al. 2014).
- The child nodes of node x are always 2x and 2x + 1, to help in navigating the tree summary (compare the summary to the bottom figure 2).
- They are many Items in the tree summary list:
 - the complexity table
 - the variable importance
 - the node number
 - the number of cases within the node
 - the number of events (number of cases with attribute 1) inside the node
 - the logistic intercept coefficient fitted inside the node, which represents the summary statistic of the node. This coefficient represents the predicted value of the node. that's the main difference with a conventional tree where the predicted value is the modal class of the node.
 - the logistic deviance of the previous model inside the node which is used as the splitting criterion

Figure 2: The figure on the top is the maximal tree obtained with pltr.glm; the figure on the bottom is a pruned tree via a BIC criterion

- * indicates that the node is terminal.
- the first split is on the Percentage of total surface area burned (Z_4) . 64 individuals with $Z_4 < 15.5$ go to the left while the remaining 90 go to the right. The split with the maximum number of events is always on the right.
- The improvement listed is the change in deviance for the split, i.e., D(parent) (D(leftson) + D(rightson)), where D is the deviance operator. This is similar to a likelihood ratio test statistic.
- the other nodes can be described similarly.

For all the two models (tree with rpart (Fig 1) and the tree with our proposed procedure (Fig 2)), the first split is due to the percentage of total surface area burned ((< 16.5%, > 16.5%) for **rpart** and (< 15.5%, > 15.5%) for the proposed method). The subsequent splits are different between patients having a high or low percentage of total surface area burned. The classical rpart model shows only one split whereas our proposed PLTR model shows two splits. With the exception of CART model where no split occurs, the subsequent split for the group of patients with a low percentage of area burned is due to the initial treatment (routine bathing/body cleansing). For high percentage of surface area burned, the split for the group of patients with a high percentage of surface area of body burned, without tract respiratory damage, buttock injury and without routine bathing shows a lower proportion of prophylactic antibiotics administration. This group is not detected by the original PLTR method. It is worth noting that the confounding factor Z2 is significant with a higher proportion of prophylactic antibiotics administration among women.

The particularity of the PLTR model is that in addition with the tree part, the final model is a classical logistic model with new risk factors emerging from the tree part. The summary of the final logistic model is presented within the R code above. We can see for example that the new risk factor constituted by individuals sharing the attributes Z4 < 15.5 and Z1 < 0.5 is highly significant (although naively due to randomness) w.r.t the reference leaf. Similar interpretation can be made for other factors.

5 Compute the generalization error of the procedure

We can further compute the generalization error of the procedure. This can be computed via the function **best.tree.CV** which can also provide the best tree based on a K-fold cross-validation procedure.

```
> set.seed(150)
> pltr.burn_CV <- best.tree.CV(pltr.burn$tree, burn, Y.name, X.names,
                    G.names, family = family, args.rpart = args.rpart,
                    epsi = 0.001, iterMax = 15, iterMin = 8, ncv = 10,
                    verbose = FALSE)
Max tree size 10 reached
Max tree size 10 reached
Max tree size 10 reached
> pltr.burn_CV$CV_ERROR
[[1]]
[1] 0.3515789
[[2]]
[1] 0.3729825 0.3649123 0.3677193 0.3810526 0.3810526
[6] 0.3624561 0.3663158 0.3515789 0.3649123
> Bic_size <- sum(pltr.burn_prun$tree$BIC$frame$var == '<leaf>')
> ## Bic_size <- tree_select$best_index[[1]]</pre>
>
> CV_ERROR_BIC <- pltr.burn_CV$CV_ERROR[[2]][Bic_size]</pre>
> CV_ERROR_BIC
[1] 0.3624561
```

The generalization error of the procedure using the BIC criterion is computed as presented in the previous r code.

6 Test the joint effect of the selected tree while adjusting for confounders.

We can also test the joint effect of the selected tree after adjusting for the confounding variable

```
args.parallel = args.parallel, index = index, verbose =
FALSE)
> p_value$P.value
```

7 Bagging a set of PLTR models

The high variability of the tree within the PLTR model can result in an unstable selected model. An ensemble method such as Bagging can stabilize the predictor. The user are encouraged to read the paper of (Mbogning et al. 2015) for a more thorough explanation about the procedure.

A flowchart of the bagging procedure related to the PLTR model is as follow:

```
> ## ?bagging.pltr
> set.seed(250)
> Bag.burn <- bagging.pltr(burn, Y.name, X.names, G.names, family,
                args.rpart,epsi = 0.01, iterMax = 4, iterMin = 3,
                Bag = 20, verbose = FALSE, doprune = FALSE)
ncores = 1 for bagging trees !
> ## The thresshold values used
>
> Bag.burn$CUT

>
> PLTR_BAG.burn <- Bag.burn$Glm_BAG
> ##The set of trees in the bagging procedure
>
> TREE_BAG.burn <- Bag.burn$Tree_BAG</pre>
> ## Look for the variability of trees in the bagging sequence
>
> par(mfrow = c(3,2))
> plot(TREE_BAG.burn[[1]], branch = .5, main = '', margin = 0.05)
> text(TREE_BAG.burn[[1]], xpd = TRUE, cex = .6 )
> plot(TREE_BAG.burn[[2]], branch = .5, main = '', margin = 0.05)
> text(TREE_BAG.burn[[2]], xpd = TRUE, cex = .6 )
> plot(TREE_BAG.burn[[3]], branch = .5, main = '', margin = 0.05)
> text(TREE_BAG.burn[[3]], xpd = TRUE, cex = .6 )
> plot(TREE_BAG.burn[[4]], branch = .5, main = '', margin = 0.05)
> text(TREE_BAG.burn[[4]], xpd = TRUE, cex = .6 )
> plot(TREE_BAG.burn[[5]], branch = .5, main = '', margin = 0.05)
> text(TREE_BAG.burn[[5]], xpd = TRUE, cex = .6 )
> plot(TREE_BAG.burn[[6]], branch = .5, main = '', margin = 0.05)
> text(TREE_BAG.burn[[6]], xpd = TRUE, cex = .6 )
```

Prediction using the bagged pltr predictor

```
> ## Use the bagging procedure to predict new features
> # ?predict_bagg.pltr
>
```

Figure 3: set of the first 6 trees within the bagging predictor: The trees seem to fluctuate with the sample considered during the resampling step.

```
> Pred_Bag.burn <- predict_bagg.pltr(Bag.burn, Y.name, newdata = burn,
                  type = "response", threshold = seq(0, 1, by = 0.1))

Compute the variable importances of the bagging procedure

Several scores for variable importance are proposed (Mbogning et al. 2015). Among them,

- the Permutation Importance Score (PIS)
- the Deviance Importance Score (DIS)
- the Depth Deviance Importance Score (DDIS)
- the minimal depth score

```
> Var_Imp_BAG.burn <- VIMPBAG(Bag.burn, burn, Y.name)

compute the AUC of the Bagged predictor based on OOB samples

Figure 4: Variable importances using the bagging procedure on the burn dataset: The permutation importance score (PIS on the left), the deviance importance score (DIS on the middle) and the depth deviance importance score (DDIS on the right).

Figure 5: Roc curve with AUC of the Bagged predictor using OOB samples.
